**ABSTRACT.** The Bombay duck, or bummalo (*Harpadon nehereus*), is a lizardfish native to the Arabian sea, but also common in the China sea. It is normally dried and salted before consumption and export. To provide molecular information on this economically important fish species, we developed and characterized microsatellite markers. Ninety positive clones from the (CA)₅-enriched genomic library were sequenced; 62 sequences contained sufficient repeat motifs (di-, tri- and tetra-nucleotide). Twenty-eight primer pairs were designed and 21 were successfully amplified; five loci were polymorphic, but with a low number of alleles (three or four). The observed and expected heterozygosities ranged from 0.3500 to 0.8421 and from 0.5244 to 0.6244, respectively. All of the five polymorphic loci were at Hardy-Weinberg equilibrium (adjusted), while linkage disequilibrium between Hane-97 and Hane-175 (P < 0.05, adjusted P value = 0.01) was significant. The low degree of polymorphism of microsatellite markers may be due to the large size of the repeat motifs. These markers will be useful for genetic diversity analysis of *H. nehereus*.

**Key words:** *Harpadon nehereus*; Microsatellite; Molecular marker
INTRODUCTION

_Harpadon nehereus_ (Synodontidae), which is usually known as the Bombay duck, despite being a lizardfish, is an inshore shallow water fish widely distributed along the coastal of China. It has been an important commercial fish for domestic use and also a valuable export item, in dried or laminated form due to its highly perishable body composition. However, no information on population genetics using molecular markers has been reported for understanding population differentiation and clarifying species identity.

Microsatellites, also known as simple sequence repeats (SSRs), are regions of DNA that exhibit short repetitive sequence motifs (Degnan and Arévalo, 2004). Microsatellites were widely employed in population genetic studies of numerous species, and this application is continuously expanding (Kohlmann et al., 2005; Mia et al., 2005). Those motifs are often composed of 1-6 bp repeats and there is often a high degree of polymorphism for different numbers of repeats. As microsatellites have some unique characteristics, such as co-dominance of alleles, high allelic diversity, and relatively simple polymerase chain reaction (PCR)-based screening methods that are reproducible, they have been widely used in recent years for population genetic studies of numerous species (Sekino and Hara, 2001; Kohlmann et al., 2005; Mia et al., 2005; Selkoe and Toonen, 2006; Liu et al., 2009). At the same time, microsatellites have been successfully used in genetic mapping and genome analysis (Chen et al., 1997; Li et al., 2000), genotype identification, variety protection seed purity evaluation (Senior et al., 1998), germplasm conservation (Brown et al., 1996), and marker-assisted breeding (Weising et al., 1998). Here, we report on the development and genetic characterization of microsatellite loci for _H. nehereus_.

MATERIAL AND METHODS

DNA extraction and enrichment for microsatellites

DNA was extracted from 36 samples collected from nine different geographic sampling sites. The nine sites are located along the East Sea and the South Sea of China (Figure 1). Total genomic DNA was isolated from the muscle tissue using the standard phenol-chloroform method with some modifications; this was subsequently dissolved in 100 μL TE buffer and then its quality was checked on a 1% agarose gel, stained with ethidium bromide, and compared with known molecular weight standards (Tiangen). DNA was stored at -20°C before use. An enriched partial genomic library for the repeat motif (CA)$_n$ was constructed using a DNA pool composed of four individuals from different sites, and following the modified FIASCO protocol (Zane et al., 2002).

The total genomic DNA pool was simultaneously digested with the _MseI_ restriction enzyme (NEB). DNA fragments ranging from 250 to 1000 bp were isolated from a 1.5% agarose gel and purified using a TIANgel Midi Purification Kit (Tiangen). These fragments were ligated to _MseI_ amplified fragment length polymorphism (AFLP) adapters OligoA (5'-TAC TCA GGA CTC AT-3') and OligoB (5'-GAC GAT GAG TCC TGA G-3') and then were amplified in a total volume of 50 μL by PCR using adaptor-specific primers (_MseI-N_: 5'-GATGAGTCCCTGAGTAAN-3'). PCR conditions were: 1X Taq DNA polymerase buffer (Tiangen), 300 ng _MseI-N_, 200 μM of each dNTPs, 0.8 μL Taq DNA
Microsatellite markers for the Bombay duck

polymerase (Tiangen, 5 U/µL) and 20 µL of a 1/10 dilution of digested-ligation DNA. The cycling conditions were 95°C for 5 min, followed by 30 cycles of 95°C for 30 s, 53°C for 30 s, and 72°C for 1 min, followed by 1 cycle of 72°C for 10 min and then holding at 10°C. The DNA fragments between 300 and 1000 bp were isolated.

Genomic DNA fragments containing SSR were captured by hybridization to (CA)$_{15}$ biotin-labeled probes. For enrichment, the adaptor-ligated DNA fragments was denatured at 95°C for 8 min, and then hybridized to biotin-labeled probes in 70 µL hybridization solution at 65°C for 30 min. The DNA hybridized to the probe was separated and captured by streptavidin magnetic beads at room temperature for 30 min, followed by nonspecific and specific washing. The final captured fragments were ligated to pMD19-T vectors (Takara), according to manufacturer instructions, then cloned using the DH5α cells, following the standard protocol.

**Primer design and PCR amplification**

Ninety positive clones, which were screened via PCR with M13-F/M13-R and (CA)$_{15}$ primers, were sequenced using M13-F primer on an ABI 3730 automated sequencer; 62 sequences contained sufficient repeat motifs (di-, tri- and tetra-nucleotide). Considering that the repeat size will affect the polymorphism, 28 primers were designed for loci containing repeat motifs (12 bp ≤ repeating size ≤ 52 bp) using the PRIMER PREMIER 5.0 software. The optimal conditions of PCR amplifications for each primer were adjusted by the annealing temperature and Mg$^{2+}$ concentration. Then, polymorphism at each locus was determined us-

---

**Figure 1.** Sample sites for the *Harpadon nehereus*. 

---
PCR amplifications were carried out in 25 μL volumes containing 1X PCR buffer (Tiangen), 2 μL dNTPs, 0.6 μL forward and reverse primers, and 0.4 μL Taq polymerase (Tiangen, 5 U/μL). The cycling conditions were 95°C for 5 min, followed by 30 cycles of 95°C for 30 s, annealing temperature (Table 1) for 30 s, and 72°C for 30 s, followed by 1 cycle of 72°C for 5 min and then holding at 4°C. PCR amplification was performed on an ABI 9700 thermal cycler.

The products of PCR amplifications were determined on 1.5% agarose gels, and then were denatured at 96°C for 8 min using denaturant (98% formamide, 10 mM EDTA, 0.25% bromophenol blue, 0.25% FF). The denatured amplified products were separated on 6% denaturing polyacrylamide gels and visualized using silver staining. A denatured pBR322 DNA/MspI molecular weight marker (Tiangen) was used as a size standard to identify alleles (Xu et al., 2009).

### Data analysis

The number of alleles, and observed (H<sub>O</sub>) and expected (H<sub>E</sub>) heterozygosities were estimated using POPGENE32 (Yeh and Boyle, 1997), and the ARLEQUIN 3.11 software (Schneider et al., 2000) was used to calculate Hardy-Weinberg equilibrium expectations and genotypic linkage disequilibrium. All results for multiple tests were corrected using the Bonferroni’s correction (Rice, 1989).

### RESULTS AND DISCUSSION

Details of the newly developed microsatellite loci are listed in Table 1. Twenty-one of the 28 primer pairs were amplified successfully and five loci were shown to be polymorphic in H. nehereus. The variability measures across 36 individuals of Bombay duck are also summarized in Table 1. The number of alleles per locus was three or four, with a mean of 3.4, and H<sub>O</sub> and H<sub>E</sub> heterozygosities ranged from 0.3500 to 0.8421 and from 0.5244 to 0.6244, respectively. The polymorphism information content per locus ranged from 0.4403 to 0.5538. Hardy-Weinberg equilibrium probability tests showed that all of the five polymorphic loci were at Hardy-Weinberg equilibrium (adjusted P value >0.01). According to pairwise tests for linkage disequilibrium, significant pairwise test values were found between Hane-97 and Hane-175 (P < 0.05, adjusted P value <0.01).

Our results suggest that H. nehereus genome has abundant microsatellites (69%), but the polymorphism of the loci was low; only five of the 21 loci showed polymorphism and the mean number of alleles was 3.4. The low polymorphism maybe due to the motif repeat size, which is thought to be related to the polymorphism per locus (Weber, 1990; Brandström and Ellegren, 2008). Some microsatellites found in H. nehereus repeated either more than 20 times or only six times, while the size of polymorphic loci in H. nehereus all ranged from 8 to 13 times, and there were many compound and imperfect types of microsatellites, which may limit the mutation rates. These polymorphic microsatellite DNA markers that we developed could be useful to evaluate genetic variation in H. nehereus.
