ABSTRACT. miR-137, a brain-enriched microRNA, is involved in the control of neuronal proliferation, differentiation, and dendritic arborization, all of which are important for proper neurogenesis and relevant to schizophrenia. miR-137 is also known to regulate many genes implicated in schizophrenia risk. Although reports have associated the miR-137 polymorphism rs1625579 with this disease, their results have been inconsistent. The aim of this meta-analysis was to evaluate the relationship between rs1625579 and schizophrenia. Data were obtained from an electronic database, and pooled odds ratios (ORs) with 95%
confidence intervals (95%CI) were used to test the association using the RevMan 5.3 software. Twelve case-control studies comprising 11,583 cases and 14,315 controls were included. An estimated lambda value of 0.46 was recorded, suggesting that a codominant model of inheritance was most likely. A statistically significant association was established under allelic (T vs G: OR = 1.15, 95%CI = 1.10-1.21, P < 0.001) and homogeneous codominant models (TT vs GG: OR = 1.32, 95%CI = 1.13-1.54, P < 0.001), but no such relationship was detected using the heterogeneous codominant model (GT vs GG: OR = 1.14, 95%CI = 0.97-1.34, P = 0.11). This meta-analysis demonstrates that the rs1625579 miR-137 genetic variant significantly increases schizophrenia risk.

**Key words:** Schizophrenia; miR-137; Single nucleotide polymorphism; Meta-analysis; Fixed-effect analysis

**INTRODUCTION**

Schizophrenia is a severe, chronic psychiatric disorder arising in late adolescence that profoundly affects neural development and disrupts key traits such as cognition and personality (van Os and Kapur, 2009). The median incidence of this disease is reported to be 15.2 per 100,000 people (McGrath et al., 2008), and its median lifetime prevalence is estimated at 480 per 100,000 patients (Simeone et al., 2015). Moreover, schizophrenia is a major cause of disability (Warner, 2009), with approximately three-quarters of patients suffering an ongoing disability with relapses (Smith et al., 2010).

Schizophrenia is a multifactorial disorder. Although its etiology is unclear, it is widely acknowledged that the development of this disease derives from a combination of genetic and environmental factors (O’Donovan et al., 2003). Some studies have shown that single nucleotide polymorphisms (SNPs) in several genes, such as those encoding vaccinia-related kinase 2 (Zhang et al., 2015), dopamine D2 receptor (Liu et al., 2012), and regulator of G-protein signaling 9 (Zhu et al., 2015) may play major roles in the development of schizophrenia. In addition, the clinical symptoms of schizophrenia are complicated, involving perception, thought, emotion, action, cognitive function, and other faculties. These vary greatly between patients, and even the same individual may exhibit different symptoms at various stages. Analysis of the psychopathological features of various psychotic disorders suggests that symptoms can be clustered into five main categories (van Os and Kapur, 2009). Therefore, if a meaningful molecular marker for schizophrenia screening can be established, at-risk carriers may be identified and corresponding early interventions provided, potentially improving prognosis.

To date, many studies have described the involvement of microRNAs (miRNAs) in nervous system regulation, including neuronal migration and differentiation, synaptic plasticity, and adult neurogenesis (Kosik, 2006). SNPs in genes encoding miRNAs such as miR-206 (rs17578796; Hansen et al., 2007) and miR-30e (rs112439044; Xu et al., 2010) may affect the properties of the transcribed sequences by altering their expression and/or maturation (Saunders et al., 2007), resulting in nervous system disorders such as schizophrenia (Hommers et al., 2015). Notably, the largest schizophrenia genome-wide association study (GWAS) carried out to date found the SNP rs1625579 (G>T), located within an intron of the miR-137 primary transcript, to be associated with this disease (Ripke et al., 2011). Lett et al.
miR-137 polymorphism and schizophrenia

(2013) also reported that North American schizophrenia patients carrying the TT genotype of this variant have reduced brain white matter density, diminished hippocampal volume, and increased lateral ventricle volume. However, other studies have not supported an association between miR-137 rs1625579 and schizophrenia or white matter microstructure (Kelly et al., 2014; Rose et al., 2014; Wang et al., 2014). Therefore, no consistent conclusion has been reached regarding the effect of this SNP on schizophrenia. The purpose of this meta-analysis was to explore the relationship between miR-137 rs1625579 and this condition.

MATERIAL AND METHODS

Identification of eligible studies

A search of the PubMed, Web of Science, Cochrane Central Register of Controlled Trials, Science Direct, Wiley Online Library, Chinese National Knowledge Infrastructure, and Wanfang Data Resource databases was conducted during August 2015 using the search terms (“miR-137” or “rs1625579”) and (“Schizophrenia”), with no limitations placed on language. All references included in the relevant studies were extensively examined for additional publications.

Inclusion and exclusion criteria

To be included in the present meta-analysis, studies had to: a) evaluate the miR-137 rs1625579 polymorphism in relation to schizophrenia; b) consist of a human case-control study; c) include patients meeting the diagnostic criteria for schizophrenia; as well as d) report detailed genotype data for the calculation of odds ratios (ORs) and 95% confidence intervals (CIs). The following were excluded from the current analysis: i) studies not based on a case-control design; ii) duplicates of previous publications; iii) abstracts, comments, reviews, posters, and editorials; and iv) reports lacking detailed genotype data. Where multiple investigations used overlapping data, the latest study was included.

Data extraction

Data for this meta-analysis were extracted according to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses guidelines, with slight modifications. Three investigators (M.L. Ou, D. Xiao, and B.H. Zhang) independently extracted the following data from eligible studies: first author, year of publication, country of origin, ethnicity, number of cases and controls, Hardy-Weinberg equilibrium (HWE) score, and allele and genotype frequencies, amongst other information. Where detailed data were lacking, we attempted to contact the corresponding author to obtain the original dataset. Studies were then excluded if the authors did not provide additional information. Any disagreement between the researchers responsible for extracting data was resolved by consensus. After extraction, the data were reviewed and compared by C.X. Jing.

Quality assessment

All included studies were assessed according to the Newcastle-Ottawa scale (NOS) criteria (Stang, 2010), which use a “star” rating system to check methodological quality with...
regard to three aspects: selection, comparability, and exposure. Scores range from zero (low) to nine stars (high). Articles scoring <5 were classified as “low quality”, and those scoring ≥5 were considered “high quality”.

**Statistical analysis**

HWE was evaluated among the control groups of each study using the chi-square test. P < 0.05 was considered to represent departure from HWE. Pooled ORs and their 95% CIs were used to assess the association between miR-137 rs1625579 and susceptibility to schizophrenia under an appropriate model using the RevMan 5.3 software (Cochrane, 2014). Pooled ORs with Z-test P values <0.05 were regarded as statistically significant. Statistical heterogeneity among studies was tested by Cochran’s Q-statistic and the I² metric (Higgins and Thompson, 2002). Values of I² > 50% and P < 0.10 were considered to indicate significant heterogeneity. In the absence of heterogeneity, a fixed-effect model (using the Mantel-Haenszel method) was used; otherwise, a random-effect model (using the DerSimonian and Laird method) was employed. A Begg’s funnel plot was generated to assess potential publication bias, and sensitivity analysis was performed with the Comprehensive Meta-analysis software (Biostat Inc., Englewood, NJ, USA).

**Per-allele and per-genotype analysis**

In our study, the T and G variants were deemed risk and non-risk alleles, respectively. Correspondingly, the TT, GT, and GG genotypes were viewed as mutant homozygous, heterozygous, and wild-type homozygous, respectively. First, we estimated the effect of the risk allele on schizophrenia susceptibility using an allelic model (T vs G). Subsequently, we used the model-free Bayesian approach (Minelli et al., 2005) to estimate genotypic effects as TT vs GG (OR₁) and GT vs GG (OR₂). The parameter lambda (λ), defined as the ratio of logOR₁ to logOR₂, was used to gauge the genetic mode of inheritance. Lambda values range from 0 to 1: λ = 0 suggests a recessive model (TT vs GT+GG); λ = 1, a dominant model (GT+TT vs GG); and if λ = 0.5, a codominant model (TT vs GG; GT vs GG) is implied. If λ > 1 or < 0, then a homozygous or heterosis model is likely, although such cases are rare (Minelli et al., 2005). WinBUGS 1.4.3 (University of Cambridge, England, UK) was used with vague prior distributions for estimation of parameters (i.e., λ and ORs). Models were run with a burn-in of 1000 iterations, followed by 10,000 iterations for parameter estimates.

**RESULTS**

**Characteristics of eligible studies**

In total, 371 relevant studies were retrieved in the initial search. Following screening, 272 records were excluded, of which 66 were duplicates, 159 irrelevant to the topic, and 47 were posters, comments, or abstracts. Thus, 99 published articles were retained. A further 76 unrelated and non-human studies were excluded by reading titles and abstracts. We then assessed the full texts of the remaining 23 publications, and excluded 11 that lacked key information or case and control data, did not concern rs1625579, or consisted of duplicate data (Figure 1). Twelve case-control studies (Ripke et al., 2011; Lett et al., 2013; Green et al.,
miR-137 polymorphism and schizophrenia

2013; van Erp et al., 2014; Guan et al., 2014; Rose et al., 2014; Wang et al., 2014; Ma et al.,
2014; Yuan et al., 2015; Strazisar et al., 2015; Kuswanto et al., 2015; Sun et al., 2015) were
therefore included in our meta-analysis, comprising 11,583 cases and 14,315 controls. Their
general characteristics are listed in Table 1, and corresponding quality scores are given in
Table S1. Genotype distributions among the control groups of all studies were consistent with
HWE (P > 0.05).

HWE = Hardy-Weinberg equilibrium. *Genome-wide association study data from Schizophrenia Psychiatric Genome-Wide Association Study (GWAS) Consortium (Ripke et al., 2011).

Association between miR-137 rs1625579 and schizophrenia susceptibility

As no heterogeneity was detected under any genetic model (P > 0.10 and F < 50%), the fixed-effect model was used. As shown in Figure 2, there was a statistically significant difference between miR-137 rs1625579 alleles and genotypes in terms of schizophrenia susceptibility under the allelic (T vs G: OR = 1.15, 95%CI = 1.10-1.21, P < 0.001) and the homogeneous codominant models (TT vs GG: OR = 1.32, 95%CI = 1.13-1.54, P < 0.001), but no such association was observed under the heterogeneous codominant model (GT vs GG: OR = 1.14, 95%CI = 0.97-1.34, P = 0.11). A λ value of 0.46 (95%CI = 0.28-0.942) suggested that a codominant inheritance mode was most likely. Sensitivity analysis (Table S2) showed that removal of any given article did not result in a significant change to the OR, suggesting that our results are reasonably stable.

A stratified analysis based on World Health Organization (WHO) regions (Table S3) revealed the same association under allelic and codominant models in the European region (T vs G: OR = 1.15, 95%CI = 1.09-1.22, P < 0.001; TT vs GG: OR = 1.31, 95%CI = 1.10-1.58, P = 0.002; GT vs GG: OR = 1.12, 95%CI = 0.94-1.34, P = 0.20), but not in the Western Pacific (T vs G: OR = 1.17, 95%CI = 1.04-1.31, P = 0.009; TT vs GG: OR = 1.49, 95%CI = 0.95-2.35, P = 0.08; GT vs GG: OR = 1.28, 95%CI = 0.80-2.05, P = 0.30) or the Americas (T vs G: OR = 1.09, 95%CI = 0.90-1.33, P = 0.36; TT vs GG: OR = 1.20, 95%CI = 0.66-2.16, P = 0.55; GT vs GG: OR = 1.11, 95%CI = 0.60-2.03, P = 0.75). This suggests that no clear relationship exists between rs1625579 and schizophrenia among populations of these latter two regions.

DISCUSSION

This meta-analysis aimed to advance our understanding of the association between miR-137 rs1625579 and susceptibility to schizophrenia. Our data demonstrated that this polymorphism is significantly associated with increased schizophrenia risk. Individuals carrying the T allele had a 15% increased risk of developing this disease compared to those with the G allele. In addition, subjects carrying the rs1625579 TT genotype were at a 32% greater risk compared to those with the GG genotype. In the stratified analysis according to WHO regions, this same relationship was observed under the allelic and codominant models among studies from countries of the European region, but not in data from the Western Pacific or the Americas. As shown in Table S3, 95% CIs relating to these latter were wider than those observed using European studies, suggesting insufficient sample sizes for data from the Western Pacific and American regions.

This analysis based on population studies showed that the miR-137 polymorphism increases schizophrenia risk, which might provide some evidence to uncover the major genetic factors involved in the pathogenesis of schizophrenia. Moreover, such variants might serve as useful markers for schizophrenia screening, allowing carriers to be identified and provided with appropriate treatment at an early stage, improving the health mentally and physically.

miR-137 is known to be a major regulator of the nervous system (Yin et al., 2014). Using bioinformatics, Wright et al. (2013) identified 1144 genes potentially targeted by this miRNA, of which 25 or more intersected with those listed in the SZGR schizophrenia gene resource database. In addition, they identified 26 miR-137-regulated genes associated with susceptibility to this disease. Sun et al. (2011) demonstrated that miR-137, revealed to be a target of TLX (a nuclear receptor transcription factor) and a novel upstream regulator of lysine-specific demethylase 1 (LSD1), forms a regulatory feedback loop with these proteins to maintain the dynamics of neural stem cell (NSC) proliferation and differentiation. TLX is an essential regulator maintaining adult NSCs in an undifferentiated and self-renewable state. It achieves this in part by recruiting and forming a complex with its corepressor LSD1, the first lysyl demethylase found to regulate histone methylation (Shi et al., 2004), before binding an miR-137 genomic region to inhibit methylation of pre-miR-137, thus downregulating expression of miR-137 (Sun et al., 2007, 2010, 2011). Remarkably, as a target of miR-137, expression of LSD1 is in turn inhibited by this miRNA. In addition, it has been shown that increased miR-137 expression leads to reduced NSC proliferation and accelerated neural differentiation in mice (Sun et al., 2011). Thus, miR-137 plays an important role in regulating these processes in NSCs. Moreover, it also participates in the control of signal transduction and neuronal maturation through effects on its target genes.

Neuronal maturation and communication lead to the establishment of functional neural circuits, and abnormalities in neural structure and function can cause brain disorders such as schizophrenia. The SNP rs1625579 is located in an intron of a primary miR-137 transcript, and may affect the expression or maturation of this miRNA (Saunders et al., 2007), thus resulting in alterations to brain function.

In our meta-analysis, the NOS quality assessment scores of all included studies were no lower than 6. Furthermore, sensitivity analysis suggested that our results were sufficiently robust, and no significant heterogeneity or publication bias was detected. In addition, this meta-analysis returned results consistent with the largest schizophrenia GWAS conducted. However, the present findings should be interpreted with caution owing to certain limitations.
First, all eligible investigations in English or Chinese were incorporated, but those published in other languages that may have met our study criteria were not included. Second, the majority of data were obtained from Asian and Caucasian populations, with black and African individuals being insufficiently represented. Additional studies are needed to investigate the influence of this SNP in other populations. Third, outcomes were based on individual unadjusted

In summary, this meta-analysis supports a clear association between the miR-137 rs1625579 SNP and schizophrenia risk. A comprehensive evaluation of gene-gene and gene-environment interactions should also be performed in future analysis.
